LOSS RATIO DISTRIBUTIONS
A MODEL

C. C. HEWITT, JR.

1. INTRODUCTION AND SUMMARY

1.1 Historical

Traditionally in casualty insurance loss ratio distributions have been obtained empirically and often at great expense and with great labor [for the most recent such effort see (13)]. Associated with collecting masses of raw data have been serious problems of fitting such data [see (8), (12) and (14)]. The end-product of all of these efforts has been non-analytical; and of value only for use in linear retrospective rating and as a rough guide to loss ratio distributions by size.

1.2 An Analytical Model

In this author's review (11) of (13) he indicated the successful fitting of a mathematical model—the gamma distribution—to actual loss ratio distributions. Also, there was indicated a relationship among the significant parameters for loss ratio distributions at various premium sizes.

1.3 Purpose and Results of this Paper

In this paper are set forth some important mathematical properties of the gamma distribution (Chapter 2) including the very important characteristic of reproducibility and divisibility. In most instances the development of formulas and lemmas is left to the reference texts, or the reader. The gamma distribution is applied directly to loss ratio distributions as a model (Chapter 3) and a single parameter form is asserted.

In Chapter 4 the method of fitting actual data is explained and the goodness of the fit is discussed. A relationship among parameters at various premium sizes is also asserted. As a corollary it becomes evident that for actual data, loss ratio distributions for larger premium sizes are not equivalent to loss ratio distributions that might have been obtained by taking random samples from smaller premium sizes. An attempt is made to account for this phenomenon.

Finally (Chapter 5) the utility of the new model is discussed for:

1. Linear retrospective rating.
2. Non-linear retrospective rating.
3. Competitive “retro” dividend plans.
1.4 Prospectus

Although significant results are obtained within this paper, the implications go far beyond the answers. For example, the gamma distribution as a loss ratio model for larger risk premium sizes must be the synthesis of:

1. Distributions of a single loss,
2. Distributions of occurrence of one or more losses, and
3. Inherent risk heterogeneity.

It would be interesting to see this analyzed further; such analysis would undoubtedly explain why the goodness-of-fit tests fail for smaller premium sizes. Hopefully, then, this paper will not be an end but merely a beginning.

2. THE GAMMA DISTRIBUTION

2.1 The Gamma Function

2.11 The (Complete) Gamma Function

(a) Definition:
\[ \Gamma(r) = \int_0^\infty x^{r-1} e^{-x} \, dx \quad [r>0] \] ............ (2.111)

(b) The (complete) gamma function has the recursive property:
\[ \Gamma(r+1) = r\Gamma(r) \] ............ (2.112)

(c) If \( r \) is integral,
\[ \Gamma(r+1) = r! \] ............ (2.113)

(d) The (complete) gamma function has a minimum when \( r \) is approximately 1.4616; the minimum is approximately 0.8856.

As \( r \) approaches zero, or increases without limit, the (complete) gamma function increases without limit.

(e) \[ \Gamma(r) \sim \sqrt{2\pi r} \frac{e^{-r}}{r^{r+\frac{1}{2}}} \]

for large \( r \) ............ (2.114)

(f) For intermediate, non-integral values of \( r \), use may be made of the recursive property (2.112) and published tables [(1), p. 316].

(g) \[ \Gamma(\frac{1}{2}) = \sqrt{\pi} \] ............ (2.115)
(h) \[ \Gamma(r) = \lim_{n \to \infty} \frac{n! n^{r-1}}{r(r + 1)(r + 2) \ldots (r + n - 1) \ldots} \ldots \quad (2.116) \]

[(3), p. 697]

(i) \[ \frac{1}{\Gamma(r)} = r e^{\gamma r} \prod_{k=1}^{\infty} \left(1 + \frac{r}{k}\right) e^{-\frac{r}{k}} \ldots \ldots \quad (2.117) \]

where \( \gamma \) is the Euler-Mascheroni constant.

\[ \gamma = \lim_{n \to \infty} \left(\sum_{k=1}^{n} \frac{1}{k} - \log n\right) = -\int_{0}^{\infty} e^{-x} \log x \, dx, \]

\[ \gamma \approx 0.5772157 \quad [(3), \text{p. 697}] \]

(j) The \( k \)th derivative of \( \Gamma(r) \) is:

\[ \Gamma^{(k)}(r) = \int_{0}^{\infty} x^{r-1} (\log x)^{k} e^{-x} \, dx \ldots \ldots \quad (2.118) \]

2.12 The Incomplete Gamma Function

(a) Definition:

\[ I(u, p) = \frac{\int_{0}^{x_0} x^{p} e^{-x} \, dx}{\Gamma(p + 1)}; \quad (p + 1 = r, \cdots, p > -1) \]

\[ \text{where } u = \frac{x_0}{\sqrt{p + 1}} \ldots \ldots \quad (2.121) \]

(b) In the gamma distribution a scale parameter, \( a \), is introduced; in this case:

\[ u = \frac{ax_0}{\sqrt{p + 1}}; \quad (a > 0) \ldots \ldots \quad (2.121b) \]

(c) Use may be made of published tables, (4). Also see [(5) p. 223] for adaptations from other published tables.

(d) For \( p \) near \(-1\), values of the incomplete gamma function may be approximated to a desired degree of accuracy by iteration of the following series [(4, p. xv):

\[ I(u, p) = \frac{\zeta^{(p+1)}}{\Gamma(p+2)} \left\{ 1 - \frac{\zeta(p+1)}{1!(p+2)} + \frac{\zeta(p+1)}{2!(p+3)} - \frac{\zeta(p+1)}{3!(p+4)} + \cdots \right\} \]

where \( \zeta = u\sqrt{p + 1} \ldots \ldots \quad (2.122) \)
2.2 The Gamma Distribution

2.21 Basic Properties

(a) Definition:
\[ \Gamma_{\alpha, \beta}(x) = \frac{\alpha^\beta}{\Gamma(\beta)} x^{\beta-1} e^{-\alpha x}, \left[ x \geq 0 \right] \quad \left[ \begin{array}{c} \alpha > 0 \\ \beta > 0 \end{array} \right] \]  \hspace{1cm} (2.211)

(b) The gamma distribution is a special case of the more general Pearson Type III distribution:
\[ f(x) = \frac{A(x - \mu)^{\gamma-2} e^{-\alpha (x - \mu)}}{\Gamma(\gamma)} \left[ x > \mu \right] \]  \hspace{1cm} (2.212)
when \( \mu = 0 \)

(c) \( \alpha \) is the trivial scale parameter
\[ (2) \text{ II, p. 46}; \beta \) is the important parameter.

(d) The mode of \( \Gamma_{\alpha, \beta}(x) \) occurs at:
\[ \frac{r - 1}{a} ; \left( \beta > 1 \right) \]  \hspace{1cm} (2.213)

(e) The characteristic function is
\[ \left( 1 - \frac{it}{a} \right)^{-\beta} \]  \hspace{1cm} (2.214)

(f) The exponential distribution:
\[ a e^{-\alpha x} \]  \hspace{1cm} (2.215)
is a special case of \( \Gamma_{\alpha, \beta}(x) \)
when \( r = 1 \)

(g) The gamma distribution is the continuous analogue of the negative binomial \[ (2) \text{ II, p. 10}. \]

(h) Estimators \( (6), \text{ p. 39}. \):
If \( r \) is given, the maximum likelihood estimator for \( a \) is:
\[ \hat{a} = \frac{r}{\bar{x}} ; \bar{x} = \text{sample mean} \]  \hspace{1cm} (2.216)

For large \( n \), the p. d. f. of \( \hat{a} \) approaches normality with mean \( \frac{a}{n} \) and variance \( \frac{a^2}{nr} \). Also the p. d. f. of \( \sqrt{r} \log \hat{a} \) approaches normality with mean \( \sqrt{r} \log a \) and variance \( \frac{1}{n} \).
2.22 Reproductivity & Divisibility (Theoretical)

(a) Convolutions:
If \(x_1\) and \(x_2\) are independent with p. d. f. \(\Gamma_{a,r_1}\) and \(\Gamma_{a,r_2}\) respectively, then
\[X = x_1 + x_2\]
is gamma-distributed with p. d. f. \(\Gamma_{a,r_1 + r_2}\)
[(2) II, p. 46, (6), p. 121, and (5), p. 225]
Similarly \(\sum x_i\) under the same conditions would have p. d. f. \(\Gamma_{a,\Sigma r_i}\). This is often expressed:
\[\Gamma_{a,r_1} \ast \Gamma_{a,r_2} \ast \ldots \ast \Gamma_{a,r_n} = \Gamma_{a,\Sigma r_i} \] ...........
Consequently the sum of the values of a random sample of size \(n\) from a gamma-distributed population,
\[z = \sum_{i=1}^{n} x_i\] has a p. d. f. \(\Gamma_{a,nr}\).

(b) Divisibility:
The "inverse" of this reproductive property of the gamma distribution is infinite divisibility, i.e. \(\Gamma_{a,r}\) is the distribution of the sum of \(n\) independent random variables with a common p. d. f. \(\Gamma_{a,\frac{r}{n}}\)
[(2) II, p. 173]

2.23 Exponential Polynomials — Moments of \(x\) and \(e^x\)

(a) Functions of \(x\) of the form:
\[Ax^n e^{-bx} \Gamma_{a,r}(x) ; \left(\begin{array}{c} n > -r \\ b > -a \end{array}\right)\]
are themselves gamma-distributions, \(\Gamma_{a+b,r+n}\).

(b) For \(\Gamma_{a,r}\)
\[E(x^k e^{-bx}) = \left(\frac{a}{a+b}\right)^r \frac{\Gamma(r+n)}{(a+b)^n \Gamma(r)} \] ...........

(c) Thus the \(k^{th}\) moment of \(x\) about the origin is:
\[E(x^k) = \frac{(r+k-1)(r+k-2)\ldots(r)}{a^k} \] ...........(2.231a)
\[E(x) = \frac{r}{a} \] ...........(2.231b)
LOSS RATIO DISTRIBUTIONS

\[ E(x^a) = \frac{(r + 1)r}{a^a} \] .......................... (2.231c)

and \[ D^a(x) = E(x^a) - \overline{E(x)} = \frac{r}{a^a} \] .......................... (2.231d)

(d) Similarly, the \( k \)th moment of \( e^x \) is:

\[ E(e^x)^k = \left( \frac{a}{a-k} \right)^r ; (a > k) \] .......................... (2.231e)

and \[ E(e^x) = \left( \frac{a}{a-1} \right)^r ; (a > 1) \] .......................... (2.231f)

etc.

(e) This latter situation is helpful if the logarithm of a variable, \( y \), is gamma-distributed, i.e.,

if, \( x = \log cy \) has p. d. f. \( \Gamma_{a,r}(x) \)

Since \( y = e^x \), the moments of \( y \) are given in (2.231e).

[See (10)].

3. GAMMA-DISTRIBUTION AS A MODEL FOR LOSS RATIO DISTRIBUTIONS

3.1 Definition of terms:

- \( L \) = actual (risk) losses ($)
- \( \epsilon \) = expected loss ratio
- \( P \) = (risk) premium ($)
- \( r^l \) = actual (risk) loss ratio = \( \frac{L}{P} \)
- \( R = \frac{\text{actual loss ratio}}{\text{expected loss ratio}} = \frac{r^l}{\epsilon} \)

3.2 The distribution form of \( R \):

If \( R \) is gamma-distributed, its p. d. f. would take the form [see (2.211)]:

\[ f(R) = \frac{a^r}{\Gamma(r)} R^{r-1} e^{-aR} ; \left( \begin{array}{c} a > 0 \\ r > 0 \end{array} \right) \] .......................... (3.21)

with \( E(R) = \frac{r}{a} \), but if total actual losses balance with total expected losses,

\[ E(R) = 1 \] by definition,

and \( a = r \); therefore

\[ f^*(R) = \frac{r^r}{\Gamma(r)} R^{r-1} e^{-rR} \] .......................... (3.21*)

with \( r \) as its own scale parameter.
3.3 The distribution form of $r'$:

From (3.21), (3.21*) and $r' = \epsilon R$

it follows that:

$$g(r') = \left( \frac{a}{\epsilon} \right)^{r'} \Gamma(r) \ r^{r'-1} e^{-\frac{a}{\epsilon} r'}$$  

\[\text{(3.31)}\]

and

$$g^{*}(r') = \left( \frac{r}{\epsilon} \right)^{r'} \Gamma(r) \ r^{r'-1} e^{-\frac{r}{\epsilon} r'}$$  

\[\text{(3.31*)}\]

with $\frac{r}{\epsilon}$ as the scale parameter.

3.4 The distribution form of $L$:

From (3.31), (3.31*) and $L = r'P$

it follows that:

$$h(L) = \left( \frac{a}{\epsilon P} \right)^{r} \Gamma(r) \ L^{r-1} e^{-\left( \frac{a}{\epsilon P} \right) L}$$  

\[\text{(3.41)}\]

and

$$h^{*}(L) = \left( \frac{r}{\epsilon P} \right)^{r} \Gamma(r) \ L^{r-1} e^{-\left( \frac{r}{\epsilon P} \right) L}$$  

\[\text{(3.41*)}\]

with $\frac{r}{\epsilon P}$ as the scale parameter.

3.5 The distribution forms of random samples:

If random samples of size $nP$ are taken (or go to make up a sample of size $P$) from the risk-population, it follows from the reproductivity and infinite divisibility property of the gamma distribution (see Section 2.22) that $L_n$, the losses in such random samples, are distributed

$$h(L_n) = \Gamma \frac{a}{\epsilon r}, nr$$  

\[\text{(3.51)}\]

and

$$h^{*}(L_n) = \Gamma \frac{r}{\epsilon r}, nr$$  

\[\text{(3.51*)}\]

where ($n > o$)

Since $r'_n = \frac{L_n}{nP}$, it follows that

$$g(r'_n) = \Gamma \frac{na}{\epsilon r}, nr$$  

\[\text{..(3.52)}\]
and
\[ g^*(r_n') = \frac{\Gamma_{nr, nr}}{\epsilon} \] ...........(3.52*)

Also
\[ R_n = \frac{r_n'}{\epsilon}, \text{ therefore} \]
\[ f(R_n) = \Gamma_{na, nr} \] ............(3.53)

and
\[ f^*(R_n) = \Gamma_{nr, nr} \] ............(3.53*)

3.6 Fitting loss-ratio data to the Gamma-distribution:
(a) As \( r \) increases \( \Gamma_{a, r} \) approaches the form of the normal distribution.
(b) Furthermore the function:
\[ r'g(r') \]
is itself of the gamma distribution form [see 2.23 (a)]
\[ \Gamma_{a, r + 1} \]
(c) Also for fixed \( P \) (premium size) \( r'g(r') \) is proportional to:
\[ Lh(L) \]
(d) This combination of (1) increased “normality”, (2) primary interest in the distribution of amount ($'s) of loss (as opposed to number of risks), and (3) the convenience of “generated” gamma-distributions of amounts of loss from gamma-distributions by number of risks suggests the following method for determining the important parameter, \( r' \):
(1) Use \( \bar{r}' \) (= sample mean loss ratio) as an estimator for \( r' \).
(2) Use \( \bar{r}'' \) (= sample mean loss ratio-weighted by amount of loss in each loss ratio interval—rather than by number of risks) as an estimator for:
\[ r'' = E(r'g(r')) = E(\Gamma_{a, r + 1}) \]
(3) Then from (2.231b)
\[ \bar{r}' = r' = \frac{\bar{r}}{a} \epsilon \]
\[ \bar{r}'' = r'' = \frac{\bar{r} + 1}{a} \epsilon \]
\[ \frac{\bar{r}''}{\bar{r}'} = \frac{\bar{r} + 1}{\bar{r}}, \text{ and} \]
\[ \hat{r} = \frac{\hat{r}'}{\hat{r}'' - \hat{r}'} \]  

and \( \hat{r} \) can be used as an estimator for \( r \).

(e) This uniquely determines the distribution—\( f^*(R) \)—for a particular premium size. The other distributions in the (*) family, \((3.31*)\) and \((3.41*)\), are known if \( \varepsilon \) is known. Furthermore the non-starred distributions, \((3.21)\), \((3.31)\) and \((3.41)\) can then be determined by using (2.216) to determine \( a \).

(f) From (2.231a) it follows that for \( g(r') \):

\[
\frac{E(x^{k+1})}{E(x^k)} = \frac{(r + k \ldots (r)e^{k+1}}{a^{k+1}} \cdot \frac{a^k}{(r + k - 1) \ldots (r)e^k} = \frac{r + k}{a} \varepsilon
\]

which, for \( k = 1 \), gives another way of obtaining \( \hat{r}'' \).

(g) In general the approach for estimating \( r \) which is described in this section is particularly appropriate for highly-skewed loss ratio distributions, since it emphasizes higher-moment-weighted distributions that are more nearly normal.

However, great care must be exercised in fitting higher-moment means to small samples because of the increased effect of infrequent and often erratic large losses and larger loss ratios upon the estimators.

4. FITTING THE GAMMA-DISTRIBUTION TO ACTUAL LOSS-RATIO DISTRIBUTIONS

4.1 The Data

(a) Fortunately, data of unusual homogeneity for its large amount was obtained by using workmen's compensation insurance experience for the single state of California—now our largest state, not only in population, but also in workmen's compensation premium volume. The data is contained in a special unpublished report of the California Inspection Rating Bureau dated January 31, 1963 entitled "California Experience Rating Statistics—Series II—By Interval of Subject Premium Loss Ratio."

(b) The raw data is tabulated in a series of fourteen exhibits by subject premium size:
and is for policies effective in the first nine months of 1958.
An extract of the significant portions of the data contained in Exhibit K is shown in Table 1 in the Appendix as an example.

(c) Determining the estimator for $r$:
Using (3.61) and the data in Table 1 for illustration of the method:

$$\bar{r}' = 0.578 \text{ (in Table 1, } \frac{\sum (5)}{\sum (3)} \text{)}$$

$$\bar{r}'' = 0.931 \text{ (in Table 1, } \frac{\sum (5) \times (6)}{\sum (5)} \text{)}$$

$$\hat{r} = \frac{0.578}{0.931 - 0.578} = 1.639 \text{ (rounded to 1.6 for use as an entry in (4))}$$

For other premium sizes:

<table>
<thead>
<tr>
<th>Subject Premium Interval</th>
<th>$\hat{r}$ (rounded)</th>
</tr>
</thead>
<tbody>
<tr>
<td>$5,000 - 7,499$</td>
<td>0.45</td>
</tr>
<tr>
<td>7,500 - 9,999</td>
<td>0.65</td>
</tr>
<tr>
<td>10,000 - 14,999</td>
<td>0.85</td>
</tr>
<tr>
<td>15,000 - 24,999</td>
<td>1.3</td>
</tr>
<tr>
<td>25,000 - 49,999</td>
<td>1.6</td>
</tr>
<tr>
<td>50,000 - 99,999</td>
<td>2.9</td>
</tr>
<tr>
<td>More than $99,999$</td>
<td>6.2</td>
</tr>
</tbody>
</table>
(d) Goodness of Fit:

In some instances the raw data was adjusted for "contamination," but such changes were minor. Despite the broadness of some of the premium intervals Chi-square tests were met for all of the premium sizes in (c). An example is given in Table 2 in the Appendix.

Premium sizes below $5,000 can not be made to satisfy Chi-square tests even with minor smoothing.

(e) Relationship between $r$ and Premium Size:

The results set forth in (c) suggest that there should be a relationship between premium size and the key gamma-distribution parameter, $r$. Although the goodness of fit for premiums below $5,000 leaves something to be desired, estimators for $r$ were calculated and a logarithmic curve of the form:

$$\log r = a + \beta \log P$$ ...................................(4.11)

was fitted by least squares. The results are tabulated below:

<table>
<thead>
<tr>
<th>Average Subject Premium Size (in interval)</th>
<th>$\hat{r}$</th>
<th>$r$</th>
</tr>
</thead>
<tbody>
<tr>
<td>Raw</td>
<td>Using (4.11)*</td>
<td></td>

<tr>
<td>$1,924$</td>
<td>.187</td>
<td>.188</td>
</tr>
<tr>
<td>$3,481$</td>
<td>.326</td>
<td>.298</td>
</tr>
<tr>
<td>$6,050$</td>
<td>.472</td>
<td>.457</td>
</tr>
<tr>
<td>$8,652$</td>
<td>.627</td>
<td>.601</td>
</tr>
<tr>
<td>$12,265$</td>
<td>.868</td>
<td>.787</td>
</tr>
<tr>
<td>$18,944$</td>
<td>1.336</td>
<td>1.104</td>
</tr>
<tr>
<td>$33,455$</td>
<td>1.639</td>
<td>1.710</td>
</tr>
<tr>
<td>$68,758$</td>
<td>2.898</td>
<td>2.985</td>
</tr>
<tr>
<td>$220,786$</td>
<td>6.145</td>
<td>7.362</td>
</tr>
</tbody>
</table>

*(For logarithms to base 10, $a = -3.264$ and $\beta = 0.773$)

The use of average premiums as representative of an entire premium interval is crude particularly in the $100,000-and-over interval. Nevertheless a relationship indicating some predictability does exist. A hasty application of the above methods to the new Table M raw data [see (13)] supports both the use of the
gamma-distribution as a model for loss ratio distributions and the use of a logarithmic curve to determine \( r \).

(f) Reproductivity and Divisibility (Actual):

In Section 3.5 it was shown that, if \( r \) is the key parameter for premium size \( P \), then a larger \((n > 1)\) or smaller \((0 < n < 1)\) random sample from the same risk-population would have the key parameter \( nr \). If the actual loss ratio distributions discussed above followed a random sampling pattern then from (4.11)

\[
\begin{align*}
(A) \quad \log r &= a + \beta \log P \\
(B) \quad \log nr &= a + \beta \log nP \\
\text{but subtracting (A) from (B)} \\
(C) \quad \log \frac{nr}{r} &= \beta \log \frac{nP}{P} \\
(D) \quad \beta &= 1
\end{align*}
\]

However, \( \beta \) was found to be 0.773 for the California data (and logarithm-base 10). Thus, it can be inferred that larger-risk loss ratio distributions cannot be obtained by a randomized pyramiding of smaller-risk loss ratio distributions and vice versa. Putting it bluntly—for loss ratio distribution purposes—two $50,000 risks don't make a $100,000 risk. Nor is a $100,000 risk for one year the same as a $50,000 risk for two years.

This result challenges formerly-used methods of arriving at loss ratio distributions for large risks [see (9)]. Also challenged is the present method of equating insurance charges for three-year retrospective rating plans with insurance charges for a one-year plan on a risk three times as large. Similarly, there would appear to be some inaccuracy in calculating the insurance charges (contained in the basic premium) in Retrospective Rating Plan D for premium sizes 50% of, and 200% of, the estimated standard premium by equating such charges to those of risks one-half, and twice, the estimated size of the risk in question.

Since the insurance charge for larger premium sizes is a small portion of the total premium and, since the margin of error in previous and current methods of computing insurance charges would also seem to be small, it is doubtful if any great harm has been, or is being, done by the methods here impugned.
Size Characteristics of Actual Loss Ratio Distributions:

Let \( r_n \) be the value of \( r \) for a sample of size \( nP \) as determined by (4.11), i.e., from actual loss ratio distributions. Then

(A) \( \log r = \infty + \beta \log P \)

(B) \( \log r_n = \infty + \beta \log nP \)

(C) \( r_n = n^\beta r \)

On the other hand, if \( \rho_n \) is the value of \( r \) for a random sample of size \( nP \):  

(D) \( \rho_n = nr \)

From (C) and (D) it follows that:

(E) \( \rho_n = n^{(1-\beta)} r_n \)

For \( 0 \leq \beta < 1 \),

where \( n > 1 \), \( \rho_n > r_n \) ............ (4.12a)

where \( \alpha < n < 1 \), \( \rho_n < r_n \) ............ (4.12b)

But the variance of \( f(R) \) [see (2.231d) and (3.21*)] is:

\[
\frac{1}{r}
\]

Thus a loss ratio distribution of larger risk size obtained by pyramid- ing a loss ratio distribution of smaller risk size on a random basis has a smaller variance \( \frac{1}{\rho_n} \) than the actual loss ratio distribution \( \frac{1}{r_n} \).

There are a number of possible explanations for this conclusion. One such explanation, which would seem logical, would run as follows:

<table>
<thead>
<tr>
<th>Risk</th>
<th>Premium (Units)</th>
<th>Frequency (Units)</th>
<th>Severity (Units)</th>
<th>(1) \times (2) \times (3)</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>1</td>
<td>1</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>B</td>
<td>1</td>
<td>1</td>
<td>2</td>
<td>2</td>
</tr>
</tbody>
</table>
When the premium for Risk A is made equal to that of Risk B by doubling the exposure units of Risk A, it seems clear that the variance of loss ratios for double-units of Risk A would be less than the variance of loss ratios for single-units of Risk B. This is so because the severity for Risk A is only one-half the severity of Risk B.

It is clear, \textit{a fortiori}, that, all other things being equal, risks with larger severities would be in the larger premium size intervals.

5. UTILIZING THE MODEL

5.1 \textit{Linear Retrospective Rating} \cite{12} pp. 52-56

Let $S_o$ = insurance charge for loss ratios exceeding $R_o$

Then
\[
S_o = \frac{\int_{R_o}^{\infty} (R - R_o)f^*(R)dR}{\int_{0}^{\infty} Rf^*(R)dR} \quad \ldots \ldots \ldots (5.11)
\]

but
\[
\int_{0}^{\infty} Rf^*(R)dR = E(R) = 1,
\]

and
\[
\int_{0}^{\infty} f^*(R)dR = 1
\]

therefore,
\[
S_o = 1 - \int_{0}^{R_o} Rf^*(R)dR - R_o[1 - \int_{0}^{R_o} f^*(R)dR] \quad \ldots \ldots \ldots (5.11a)
\]

but
\[
\int_{0}^{R_o} f^*(R)dR = l(u_o, p)
\]
\[
\int_{0}^{R_o} Rf^*(R)dR = l(u_t, p + 1)
\]

and
\[
\int_{0}^{R_o} R^t f^*(R)dR = l(u_t, p + i)
\]

where
\[
r = p + 1
\]
\[
u_t = \frac{rR_o}{\sqrt{r + i}}
\]

see section 2.12 a & b
Thus
\[ S_o = 1 - l(u_1, p + 1) - R_o [1 - l(u_0, p)] \] ......(5.116)

Similarly if \( S_o' \) = insurance saving from loss ratios less than \( R_o \)
\[ S_o' = \frac{\int_o^{R_o} (R_o - R)f^*(R)dR}{\int_o^{\infty} Rf^*(R)dR} \] ......(5.12)
\[ S_o' = R_o \int_o^{R_o} f^*(R)dR - \int_o^{R_o} Rf^*(R)dR \] ......(5.12a)
and
\[ S_o' = R_o l(u_o, p) - l(u_1, p + 1) \] ......(5.12b)
also
\[ S_o' = S_o + R_o - 1 \] ......(5.13)

The advantages of being able to compute insurance charges (or savings) by a relatively simple formula which requires only one parameter, when the parameter is a simple logarithmic function of premium size, are many and obvious. It should be sufficient to point out that parameterization of loss ratio distributions would eliminate huge tables of ratios and charges, would lend itself to computerization and would permit different and more appropriate insurance charges among various lines of insurance, geographical territories, classifications of risk, and even between one year and the next.

5.2 Non-Linear Retrospective Rating

Inflexibility with respect to arriving at insurance charges is not the only rigidity imposed by linear forms of retrospective rating. Linear retrospective rating implies a minimum premium and a maximum premium with the intermediate values expressed as a linear function of risk losses, i.e.,
\[ P = c_t R + c_o \], but
\[ c_t = \frac{\bar{P} - P}{R - \bar{R}} \] and \[ c_o = \frac{\bar{R}P - RP}{R - \bar{R}} \]
where \( P = \) minimum premium
\( \bar{P} = \) maximum premium
With $R$ and $\bar{R}$ corresponding to the respective $P$'s

These requirements limit the insured and insurer in their choice of values for linear plans.

Why not

$$P = c_1 R^n e^{-b_1 R} + c_2 R^n e^{-b_2 R} + \ldots$$

As long as $n_i > -r$ and $b_i > -r$

[see Section 2.23 (a)], insurance charges are calculable with the knowledge of $r$.

Of course there are common sense restrictions on

$$P = F(R)$$

such as

$$F'(R) \geq 0 \quad (0 < R \leq R \leq \bar{R})$$

[see (7)].

### 5.3 Competitive “Retro” Dividend Plans

Finally, it now becomes possible to design a retrospective dividend scale to be most competitive for the most desirable risks. This is not the same as saying most competitive for risks with a zero loss-ratio, since for larger premium sizes there are very few risks with near-zero loss ratios. Rather, if a competitor’s dividend formula produces a net premium:

$$P = c_1 R + c_o \quad (P \leq P \leq \bar{P})$$

then choose a

$$P' = F(R)$$

such that

$$\psi = \int_{\bar{P}}^{\bar{P}} [c_1 R + c_o - F(R)] f(R) RdR + (P - \bar{P}) I(u, p) + (\bar{P} - P') [1 - I(\bar{u}, p)]$$

is a maximum. Of course, the correct insurance charges must be made.

(The expression for $\psi$ is a deliberate over-simplification since $R$, $R'$, $\bar{R}$, and $\bar{R}'$ will almost certainly not be equal. However, the principle is the same).
